# QUANTITATIVE EVALUATION OF THE BRONCHOCONSTRICTOR ACTION OF CURARE IN THE ANESTHETIZED PATIENT: A PRELIMINARY REPORT • CHARLES M. LANDMESSER, M.D., J. GERARD CONVERSE, M.D., AND MEREL H. HARMEL, M.D. Albany, New York Received for publication November 14, 1951 The bronchoconstrictor action of curare has been recorded and studied

THE bronchoconstrictor action of curare has been recorded and studied in the spinal dog (1) and in the decerebrate guinea pig (2). although it has been observed in the anesthetized patient (3, 4) and produced in the human volunteer (2), the bronchoconstrictor action of curare in man has been neither recorded nor thoroughly studied.

The present study was initiated in an attempt to record and evaluate quantitatively the bronchoconstrictor action of curare in the anesthetized patient under ordinary clinical conditions. A small group of patients has been studied to date, and, although the limited data thus far obtained are not suitable for statistical analysis, typical kymegraphic tracings which have been recorded are of interest.

# Метнор

The present study was conducted according to the basic principles of a method previously described (5) for recording the effect of various agents upon the caliber of the human bronchial tree. The employment of this method depends upon an apparatus which will maintain autiomatic controlled respiration (6, 7) at a constant rate and force in the anesthetized patient and record changes in the tidal volume under these conditions. The apparatus originally designed to accomplish this (fig. 1) was simplified and refined for the present study (fig. 2) without changing the basic principles of operation.

All subjects were surgical patients for whom endotracheal anesthes with a completely closed system was selected. Various combinations of preoperatitve medication and anesthetic agents were employed to facilitate endotracheal intubation and controlled respiration, but curafe was not administered until after the patient had been intubated and automatic controlled respiration at a constant rate and force had been instituted. As soon as automatic controlled respiration was estab-

lished, anesthesia was kept at as constant a level as possible while a control kymographic tracing of the tidal volume was recorded. without interrupting the tracing and before the surgical incision was made, d-tubocurarine chloride, 15 to 24 mg. (100 to 160 units), was administered by rapid (2) intravenous injection.

Under the conditions of these experiments, any changes in the tidal volume, as recorded and measured on the kymographic tracings, reflected changes in the effective bronchial caliber (5), that is, the over-all resistance to inflation of the lungs by automatic controlled

respiration at a constant rate and force.

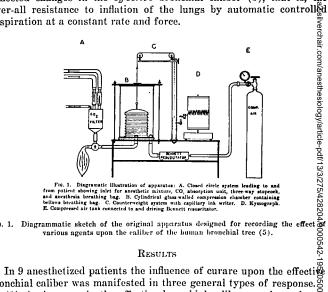

Fig. 1. Diagrammatic sketch of the original apparatus designed for recording the effect

bronchial caliber was manifested in three general types of response.

- (1) An increase in the effective bronchial caliber, as shown by an increased tidal volume, occurred in 3 patients (fig. 3). This type of response is attributed to a decreased resistance to inflation of the lungs produced by the relaxant effect of curare upon the thoracic and agdominal muscles and the diaphragm in the absence of concomitate bronchoconstriction.
- (2) Little or no change in the effective bronchial caliber, as reflected in the tidal volume, occurred in 5 patients (fig. 4). It is possible that in these cases the decreased resistance to inflation of the lungs usually produced by the relaxant effect of curare upon the thoracic and alldominal muscles and the diaphragm was nullified by a mild bronch constrictor response.

Fig. 2. The simplified and refined apparatus employed for recording the bronchocomp strictor action of curare in this study. The large tank of compressed oxygen delivers intermittent positive pressure at a constant rate and force to the compression chamber (constructed from a McKesson Metabolor, Model 175) to by virtue of a pneumatic balance resuscitator (8) which acts as a cycling device. The intermittent positive pressure is exerted upon a calibrated bellows breathing bag (enclosed within the compression chamber) to produce automatic comtrolled respiration at a constant rate and force through the closed circle absorption system of the anesthesia machine. Excursions of the calibrated bellows breathing bag are recorded directly upon a telechron kymograph by a capillary ink writer incorporated in the counter weight system.

(3) A decrease in the effective bronchial caliber, as manifested by 2 diminished tidal volume immediately following the intravenous administration of d-tubocurarine chloride, 21 mg. (140 units), occurred in one patient (fig. 5). This type of response is attributed to bronche constriction of a magnitude sufficient to increase the resistance to infla-

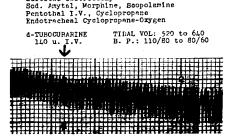

Fig. 3. Kymographic record showing the type of response characterized by an increase in the effective bronchial caliber following the intravenous administration of d-tubocurazine chloride, 21 mg. (140 units). The tidal volume increased from 520 cc. to 640 cc. while the blood pressure fell from 110/80 mm. to 80/60 mm. of mercury (cach small square represses 80 cc. of tidal air vertically and six seconds of time borizontally).

tion of the lungs in spite of the accompanying relaxant effect of curage upon the thoracic and abdominal muscles and the diaphragm.

# COMMENT

The evidence thus far obtained suggests that the response of the human bronchial tree to the intravenous administration of curare during anesthesia is variable and unpredictable. So far, a frank bronches

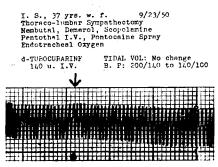

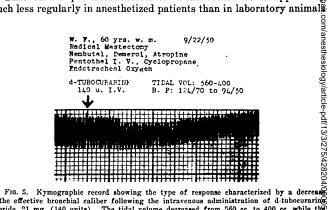

Fig. 4. Kymographic record showing the type of response characterized by little or so change in the effective bronchial caliber following the intravenous administration of tubocurarine chloride, 21 mg. (140 units). The tidal volume remained constant at 640 New while the blood pressure fell from 200/140 mm. to 140/100 mm. of mercury (each small square represents 80 cc. of tidal air vertically and six seconds of time horizontally).

constrictor response has been recorded only once. Because of the apparently infrequent occurrence of detectable bronchoconstriction for lowing the intravenous administration of curare in anesthetized pa tients, it has been impossible as yet to attempt a thorough study of its mechanism in human beings. However, it is likely that when bronchos spasm caused by curare does occur in the anesthetized patient its mechanism is on a histamine-liberating basis since there is evidence that curare produces histaminic reactions in human beings (9, 10) as well as in animals (1, 2, 11, 12).

That curare produces detectable bronchoconstriction apparently much less regularly in anesthetized patients than in laboratory animal

in the effective bronchial caliber following the intravenous administration of d-tubocuraring chloride, 21 mg. (140 units). The tidal volume decreased from 560 cc. to 400 cc. while the blood pressure fell from 124/70 mm, to 94/50 mm, of mercury (each small square represents) 80 cc. of tidal air vertically and six seconds of time horizontally).

(1, 2) is fortunate, but the reason for this difference remains to be ex plained. It is possible that the explanation is simply one of species difference. On the other hand, it is also possible that the explanation is one of differences in experimental methods, that is, in the spina? animal, which is completely flaccid to begin with, the muscle relaxant effect of curare cannot mask a bronchoconstrictor response as it may in the anesthetized patient. Still other possibilities which might be further explored are suggested by reports relating to the depressant effects of certain anesthetic agents and methods upon the liberation and action of histamine (14-19).

6 Miller (13) stated: "The lungs of the guinea pig contain, proportionally, a larger, amount of smooth muscle than those of any other animal I have studied. It is the presence of this large amount of muscle in the bronchial tree and in the pleura that makes the lung of the guines pig so difficult to distend."

Summary

An apparent bronchoconstrictor response to the intravenous administration of d-tubocurarine chloride in the anesthetized patient has been recorded. Variations in this response have been described.

Detectable bronchoconstriction following the intravenous administration of d-tubocurarine chloride apparently occurs much less re\u222ularly in the anesthetized patient than in the laboratory animal. sible explanations for this are suggested.
