# Volatile Anesthetic Actions on Contractile Proteins in Membrane-permeabilized Small Mesenteric Arteries 

Takashi Akata, M.D., Ph.D.,* Walter A. Boyle III, M.D. $\dagger$

Background: Volatile anesthetics have been shown to have vasodilating or vasoconstricting actions in vitro that may contribute to their cardiovascular effects in vivo. However, the precise mechanisms of these actions in vitro have not been fully elucidated. Moreover, there are no data regarding the mechanisms of volatile anesthetic action on small resistance arteries, which play a critical role in the regulation of blood pressure and blood flow.

Methods: With the use of isometric tension recording methods, volatile anesthetic actions were studied in intact and $\beta$ -escin-membrane-permeabilized smooth muscle strips from rat small mesenteric arteries. In experiments with intact muscle, the effects of halothane $(0.25-5.0 \%)$, isoflurane $(0.25-5.0 \%)$, and enflurane $(0.25-5.0 \%)$ were investigated on high $K^{+}$-induced contractions at $22^{\circ} \mathrm{C}$ and $35^{\circ} \mathrm{C}$. All experiments were performed on endothelium-denuded strips in the presence of $3 \mu \mathrm{~m}$ guanethidine and $0.3 \mu \mathrm{~m}$ tetrodotoxin to minimize the influence of nerve terminal activities. In experiments with membrane-permeabilized muscle, the effects of halothane ( $0.5-4.0 \%$ ), isoflurane ( $0.5-4.0 \%$ ), and enflurane ( $0.5-4.0 \%$ ) on the half-maximal and maximal $\mathrm{Ca}^{2+}$-activated contractions were examined at $22^{\circ} \mathrm{C}$ in the presence of $0.3 \mu \mathrm{M}$ ionomycin to eliminate intracellular $\mathrm{Ca}^{2+}$ stores.

Resuits: In the high $\mathrm{K}^{+}$-stimulated intact muscle, all three anesthetics generated transient contractions, which were fol-

[^0]lowed by sustained vasorelaxation. The $I C_{50}$ values for this vasorelaxing action of halothane, isoflurane, and enflurane $\stackrel{\text { ? }}{\underset{\sim}{0}}$ were $0.47 \mathrm{vol} \% ~(0.27 \mathrm{~mm}), 0.66 \mathrm{vol} \% ~(0.32 \mathrm{~mm})$, and $0.53 \mathrm{vol} \%$ ( 0.27 mm ), respectively, at $22^{\circ} \mathrm{C}$ and were $3.36 \mathrm{vol} \%(0.99 \mathrm{~mm})$, $\stackrel{N}{n}_{\sim}^{\sim}$ $3.07 \mathrm{vol} \%(0.69 \mathrm{~mm})$, and $3.19 \mathrm{vol} \%$ ( 0.95 mm ), respectively, at $\stackrel{\Phi}{\stackrel{\rightharpoonup}{\circ}}$ $35^{\circ} \mathrm{C}$. Ryanodine ( $10 \mu \mathrm{~m}$ ) eliminated the anesthetic-induced contractions but had no significant effect on the anestheticinduced vasorelaxation in the presence of high $\mathrm{K}^{+}$. In addition, no significant differences were observed in the dose depen- $\stackrel{\rightharpoonup}{0}$ dence of the direct vasodilating action among these anesthetics $\underset{\sim}{\underset{\sim}{*}}$ with or without ryanodine at either the low or the high tem- $-\frac{\rho}{0}$ perature. However, significant differences were observed inge the vasoconstricting actions among the anesthetics, and the $\frac{0}{\square}$ order of potency was halothane $>$ enflurane $>$ isoflurane. The $\frac{\stackrel{T}{\top}}{\frac{1}{\infty}}$ $\mathrm{Ca}^{2+}$-tension relation in the membrane-permeabilized muscle $\frac{0}{\infty}$ yielded a half-maximal effective $\mathrm{Ca}^{2+}$ concentration ( $\mathrm{EC}_{50}$ ) of $\frac{\mathrm{\omega}}{\mathrm{\omega}}$ $2.02 \mu \mathrm{M}$. Halothane modestly but significantly inhibited $3 \mu \mathrm{M}$ (approximately the $\mathrm{EC}_{50}$ ) and $30 \mu \mathrm{M}$ (maximal) $\mathrm{Ca}^{2+}$-induced ${ }_{\infty}^{\infty}$ contractions. Enflurane slightly but significantly inhibited $3 \underset{\sim}{A}$ $\mu \mathrm{M}$ but not $30 \mu \mathrm{M} \mathrm{Ca}$ icantly inhibit either $3 \mu \mathrm{~m}$ or $30 \mu \mathrm{M} \mathrm{Ca}{ }^{2+}$ contractions.

Conclusions: Halothane, isoflurane, and enflurane have both vasoconstricting and vasodilating actions on isolated small|$\stackrel{\bullet}{\circ}$ splanchnic resistance arteries. The direct vasoconstricting ac-0. tion appears to result from $\mathrm{Ca}^{2+}$ release from the ryanodine ${ }_{8}$ sensitive intracellular $\mathrm{Ca}^{2+}$ store. The vasodilating action of 8 isoflurane in the presence of high $\mathrm{K}^{+}$appears to be attributabl $\stackrel{\stackrel{N}{\mathrm{~N}}}{ }$ mainly to a decrease in intracellular $\mathrm{Ca}^{2+}$ concentration, pos ${ }_{-}^{\circ}$ sibly resulting from inhibition of voltage-gated $\mathrm{Ca}^{2+}$ channelso In contrast, the vasodilating actions of halothane and enflur둥 ane in the presence of high $\mathrm{K}^{+}$appears to involve inhibitiorb of $\mathrm{Ca}^{2+}$ activation of contractile proteins as well as a decrease in intracellular $\mathrm{Ca}^{2+}$ concentration in smooth muscle. (Key, words: Anesthetics, volatile: enflurane; halothane; isoflurane $\underset{N}{N}$ Artery: resistance. Membrane, permeabilization: $\beta$-escin. Mus cle, smooth: vascular.)

VOLATILE anesthetics are known to affect cardiovascular stability by causing changes in vascular reactivity, cardiac function, and autonomic reflexes that detect alterations and initiate adjustments in the cardiovascular system. ${ }^{1-3}$ Their overall effect is a decrease in mean arterial pressure caused by peripheral vasodilation, myocardial depression, and decreased sympathetic nervous system activity. ${ }^{1-3}$ Vasodilating or vasocon-
stricting actions of volatile anesthetics have been demonstrated in isolated aorta and coronary arteries, ${ }^{4-10}$ suggesting that direct vascular action may contribute to the cardiovascular effects of volatile anesthetics in vivo. In addition, recent studies have demonstrated that volatile anesthetics have vasodilating or vasoconstricting actions on isolated small resistance arteries at clinically relevant concentrations, ${ }^{11-13}$ more strongly suggesting that direct actions on vascular tissue do significantly contribute to changes in peripheral vascular resistance in vivo.

The precise mechanism(s) of the in vitro vasodilating or vasoconstricting actions of volatile anesthetics have not been fully clarified. The involvement of endothelium in the vascular actions of volatile anesthetics have been investigated in several vascular preparations, ${ }^{4-8,11,12,14-19}$ and the endothelium dependence of the vasodilating or vasoconstricting actions of halothane, enflurane or isoflurane have been suggested in some preparations including canine coronary and mesenteric arteries and rat aorta. ${ }^{4,6,14}$ In addition, several groups of investigators have demonstrated that halothane, isoflurane, enflurane, and sevoflurane can inhibit endothelium-mediated relaxations in a variety of vascular preparations. ${ }^{12,16-18}$ However, the lack of effects of endothelial denudation or the endothelium-derived relaxing factor pathway inhibitors on vasodilating actions of isoflurane or halothane has also been documented in some vascular preparations including rat aorta, rabbit basilar and canine cerebral arteries. ${ }^{7.15,19}$ Thus, the role of endothelium in the vascular responses to volatile anesthetics appears to be still controversial.

Vasodilating or vasoconstricting actions of volatile anesthetics have also been documented in several endothelium-denuded vascular preparations. ${ }^{5-8,10,14,15,19,20}$ Several previous studies that have addressed the mechanisms of the direct vascular smooth muscle actions of volatile anesthetics have suggested that these agents may affect both activation of contractile proteins and intracellular $\mathrm{Ca}^{2+}$ mobilization. ${ }^{5,14,20-24} \mathrm{Su}$ and Zhang demonstrated that halothane slightly depressed maximal $\mathrm{Ca}^{2+}$-activated tension in membrane-permeabilized rabbit aortic tissue, ${ }^{5}$ suggesting that inhibition of contractile proteins may contribute to the vasodilating action of halothane. Buljubasic and coworkers, using the patch-clamp method, have demonstrated that halothane ( $0.75 \%$ and $1.5 \%$ ) and isoflurane (2.6\%) inhibit long-lasting $\mathrm{Ca}^{2+}$ currents in canine coronary and cerebral arteries, suggesting that volatile anes-
thetics can decrease intracellular $\mathrm{Ca}^{2+}$ concentration $\left(\left[\mathrm{Ca}^{2+}\right]_{\mathrm{i}}\right)$ by inhibiting voltage-gated $\mathrm{Ca}^{2+}$ influx. ${ }^{22,23}$ More recently, Tsuchida et al. have demonstrated that halothane ( $\geq 1 \%$ ) and isoflurane ( $\geq 2 \%$ ) decreased both agonist- and high $\mathrm{K}^{+}$-induced increases in $\left[\mathrm{Ca}^{2+}\right]_{\mathrm{i}}$ in rat aortic tissues, and, by using simultaneous measurements of tension and $\left[\mathrm{Ca}^{2+}\right]_{i}$, also implied that higher concentrations of the anesthetics may inhibit $\mathrm{Ca}^{2+}$-activation of contractile proteins. ${ }^{20}$
Small splanchnic resistance arteries are known to play a critical role in the regulation of systemic blood pressure and splanchnic blood flow, ${ }^{25,26}$ and may be an important site of volatile anesthetic action. ${ }^{27}$ In addition, maintenance of splanchnic blood flow during the perioperative period may be important in preventing splanchnic ischemia, which can significantly affect the outcome of critically ill surgical patients by allowing bacterial translocation across the gut wall. ${ }^{28-30} \mathrm{Al}$ though a few previous studies have investigated volatile anesthetic action in isolated large mesenteric arteries, ${ }^{14.31}$ little information is available regarding mechanisms of volatile anesthetic action in small splanchnic resistance arteries. Previous studies in vivo and in vitro have demonstrated significant differences in the vascular actions of volatile anesthetics between large conductance and smaller arteries, ${ }^{9,27,32-34}$ indicating the need to further investigate volatile anesthetic action in the small splanchnic resistance arteries.
In this study, we investigated the mechanisms of volatile anesthetic action on small splanchnic resistance arteries. Using isometric-tension recording methods, we first investigated the vasoconstricting and vasodilating actions of halothane, isoflurane, and enflurane in endothelium-denuded tissues precontracted with high $\mathrm{K}^{+}$. We then investigated the mechanisms of these effects in ryanodine-treated intact smooth muscle and $\beta$-escin-permeabilized smooth muscle. This report represents the first description of volatile anesthetic action on $\mathrm{Ca}^{2+}$-activated contractions in membranepermeabilized resistance arteries.

## Materials and Methods

## Tissue Preparation for Tension Measurement

After receiving institutional approval for this animal study, Sprague-Dawley rats (200-250 g) were anesthetized with halothane in $\mathrm{O}_{2}$ after preoxygenation with $100 \% \mathrm{O}_{2}$ for $3-5 \mathrm{~min}$. After obtaining an optimal anesthetic level, the mesenteric tissue was removed and
immediately placed in a dissecting chamber filled with 4－（2－hydroxyethyl）piperazine－1－ethanesulfonic acid （HEPES）－buffered physiologic salt solution．The mes－ enteric artery was then rapidly excised．The distal por－ tion of the third or fourth order branch（0．15－0．20 mm in diameter）of the mesenteric artery was used． Under a binocular microscope，the surrounding con－ nective and fat tissues were removed，the vessel was cut open lengthwise，and the endothelium was re－ moved by gently rubbing the intimal surface with the round surface of a small pin as has previously been described．${ }^{35,36}$ From this＂vascular sheet，＂a transverse strip（ $150-200 \mu \mathrm{~m}$ in width， $250-400 \mu \mathrm{~m}$ in length） was prepared．Both ends of the strip were then tied with two thin silk threads，and，for the isometric tension measurement，the strip was fixed between one end of a chamber（ 0.9 ml capacity）and a L－shaped stainless rod connected to the strain－gauge transducer（UL－2， Shinko，Tokyo）as previously reported ${ }^{12,35,36}$ After a $30-\mathrm{min}$ equilibration，the strip was stretched to ap－ proximately 1.1 times its resting length（without ten－ sion）to obtain a maximal contractile response to high $\mathrm{K}^{+}$．The functional removal of the endothelium was confirmed by disappearance of endothelium－dependent relaxation by acetylcholine（ $10 \mu \mathrm{M}$ ）．The solution was changed by perfusing it rapidly from one end while aspirating it simultaneously from the other end．Ex－ periments with intact muscle were conducted both at room temperature $\left(22^{\circ} \mathrm{C}\right)$ and at $35^{\circ} \mathrm{C}$ ，whereas the experiments with membrane－permeabilized muscle were performed at room temperature $\left(22^{\circ} \mathrm{C}\right)$ to pre－ vent deterioration of the permeabilized strips．

## Solutions and Drugs

The millimolar ionic concentrations of the HEPES－ buffered physiologic salt solution（PSS）for the exper－ iments with intact muscle were as follows： NaCl 138 ， $\mathrm{KCl} 5.0, \mathrm{MgCl}_{2} 1.2, \mathrm{CaCl}_{2} 1.5$, HEPES 10，glucose 10. The $p$ H was adjusted with NaOH to 7.35 at either $22^{\circ} \mathrm{C}$ or $35^{\circ} \mathrm{C}$ ．The high $-\mathrm{K}^{+}$solutions were prepared by re－ placing NaCl with KCl isoosmotically．
The composition of the relaxing and activating so－ lutions used in the experiments with membrane－per－ meabilized muscle are listed in table 1，which also shows calculated values of free ion concentrations and total ionic strength in each solution．The $p \mathrm{H}$ was ad－ justed with KOH to 7.00 at $22^{\circ} \mathrm{C}$ ．Free ion concentra－ tions and the ionic strengths of the relaxing and acti－ vating solutions were calculated by solving multiequi－ librium equations with a hydrogen ion activity
coefficient 0.75 and association constants between ions （Appendix）as previously used．${ }^{37,38}$ Numerical solution of a set of multiequilibrium equations was achieved by a successive approximation method by computer （Powerbook 170，Apple，Cupertino，CA）．
Guanethidine，tetrodotoxin，HEPES，$\beta$－escin，and io－ nomycin were obtained from Sigma Chemical（St． Louis，MO）．Ethyleneglycol－bis－（ $\beta$－aminoethyl ether）－ $\mathrm{N}, \mathrm{N}, \mathrm{N}^{\prime}, \mathrm{N}^{\prime}$－tetraacetic acid（EGTA），piperazine－1，4－bis－－률 （2－ethanesulfonic acid）（PIPES－K $\mathrm{K}_{2}$ ），and methanesul－${ }^{-}$ fonic acid were obtained from Fluka Chemie $\mathrm{AG}_{\overrightarrow{3}}^{\vec{B}}$ （Buchs，Switzerland）．Ryanodine was purchased fromf Agri Systems International（Wind Gap，PA）．Isoflurane⿳亠二口̄⿱心夊心． and enflurane were obtained from Abbott Laboratories （North Chicago，IL），and halothane was obtained from Ayerst Laboratories（Philadelphia，PA）．All other re $\frac{\stackrel{\rightharpoonup}{2}}{\bar{i}}$ agents were of the highest grade commercially avail $\frac{.0}{3}$ able．

## Experimental Design

Intact Muscle．The effects of halothane，isoflurane and enflurane on maximum high $\mathrm{K}^{+}$－induced contrac $\frac{\frac{\rightharpoonup}{⿳ ㇒}}{\frac{\circ}{\circ}}$ tions were studied in endothelium－denuded strips al⿳亠口冋⿱十又⿴⿱冂一⿰丨丨丁心 room temperature $\left(22^{\circ} \mathrm{C}\right)$ and at $35^{\circ} \mathrm{C}$ ．To suppress． peripheral nerve activities， $3 \mu \mathrm{~m}$ guanethidine and 0.3 合 $\mu \mathrm{M}$ tetrodotoxin were present in the solutions through ${ }_{⿷ 匚 ⿳ 口 十 ⿴ 囗 十 丌}^{\text {an }}$ out the experiments．In the experiments at room tem $\vec{\rightharpoonup}$ perature，the volatile anesthetics were cumulativelyg （ $0.25-5.0 \%$ ）applied to the strip after contractile re sponse to 143 mm K had reached a plateau．Because $\stackrel{\rightharpoonup}{\mathrm{G}}_{\mathrm{G}}$ the 40 mm K －induced contractions were often not well面 maintained for a long period at $35^{\circ} \mathrm{C}$ ，a single concen． tration（ $0.125-5.0 \%$ ）of each anesthetic was appliect to the strip after contractile response to 40 mm K reached a plateau．The anesthetics were not cumula tively applied in these experiments（at $35^{\circ} \mathrm{C}$ ）．
Because the above experiments revealed that the vol $\stackrel{\circ}{\circ}$ atile anesthetics had a vasoconstricting action that re： sulted from $\mathrm{Ca}^{2+}$ release from intracellular $\mathrm{Ca}^{2+}$ stores as previously demonstrated，${ }^{11-13}$ we also examined the ${ }^{\text {en }}$ effects of volatile anesthetics on ryanodine－treated strips at both temperatures．In these experiments，ryanodine $(10 \mu \mathrm{M})$ was first applied to the strips with caffeine $(20 \mathrm{~mm})$ for approximately 1 min to deplete the $\mathrm{Ca}^{2+}$ stores，and the strips were then treated with ryanodine （ $10 \mu \mathrm{~m}$ ）－containing PSS for 25 min ．All the experiments with ryanodine were started after 20 mm caffeine－in－ duced contractions were completely abolished．
Membrane－permeabilized Muscle．After measuring steady contractions induced by high $\mathrm{K}^{+}$，the strips were

$\mathrm{pCa}=-\log \left[\mathrm{Ca}^{2+}\right] ;$ EGTA $=$ ethyleneglycol-bis $(\beta$-aminoethyl ether $)-N, N^{\prime}$-tetraacetic acid; $\mathrm{Ms}=$ methanesulfonate; $\mathrm{PIPES}=$ piperazine- $N-N^{\prime}$-bis- $(2$-ethanesulfonic acid); ATP = adenosine $5^{\prime}$-triphosphate; $\mathrm{CrP}=$ creatinine phosphate. The pH was adjusted with KOH at $7.0\left(22^{\circ} \mathrm{C}\right)$.
permeabilized with $50 \mu \mathrm{~m} \beta$-escin for $22-24 \mathrm{~min}$ at room temperature in relaxing solution. ${ }^{39-41}$ Low concentrations of $\mathrm{Ca}^{2+}$ ionophores such as ionomycin or A23187 have been used to achieve nonselective and functional depletion of the intracellular $\mathrm{Ca}^{2+}$ store. ${ }^{35,40-43}$ In fact, in this artery, $0.3 \mu \mathrm{M}$ ionomycin was effective in abolishing caffeine ( 20 mm )- and phenylephrine ( $10 \mu \mathrm{M}$ )-induced contractions in $\mathrm{Ca}^{2+}$-free ( 2 mm EGTA) solutions in intact strips, and in abolishing the caffeine contractions in $\beta$ -escin-permeabilized strips. Therefore, all of the experiments with membrane-permeabilized muscle were performed in the presence of $0.3 \mu \mathrm{M}$ ionomycin to deplete the intracellular $\mathrm{Ca}^{2+}$ stores.
In the first set of experiments with membrane-permeabilized muscle, we determined the pCa -tension relation by applying various concentrations of $\mathrm{Ca}^{2+}$ containing activating solutions in a cumulative manner. In another set of the experiments, we examined the effects of halothane, isoflurane, and enflurane at concentrations of $0.5-4.0 \%$ on the half-maximal and max-
imal $\mathrm{Ca}^{2+}$-activated contractions. The volatile anesthetics were applied to the strips in a cumulative manner after the $\mathrm{Ca}^{2+}$-activated contractions reached a plateau ( 5 min after application of $\mathrm{Ca}^{2+}$ ); each concentration of each anesthetic was applied for a period of 2 min .

## Volatile Anesthetics: Delivery and Analysis

The volatile anesthetics were delivered by agent-specific vaporizers in line with the air gas aerating the solutions in experiments with intact and with mem-brane-permeabilized muscle. Each solution was equilibrated with the anesthetics for at least 10 min before introduction to the chamber, which was covered with thin glass to prevent the equilibration gas from escaping into the atmosphere. The anesthetic concentrations in the solutions were determined by gas chromatography (fig. 1).
Although the actual concentrations of volatile anesthetics in the PSS were not measured in all experiments,

Fig. 1. Measured concentrations of $(A)$ halothane, ( $B$ ) isoflurane, and (C) enflurane dissolved in various solutions at $22^{\circ} \mathrm{C}$ or $35^{\circ} \mathrm{C}$. The predicted values (dotted lines) were calculated from the wa-ter-gas partition coefficient at $25^{\circ} \mathrm{C}(1.20$ for halothane) or from Krebs' solutiongas partition coefficients at $37^{\circ} \mathrm{C}(0.75$, 0.55 and 0.74 for halothane, isoflurane, and enflurane, respectively). ${ }^{44}$ The wa-ter-gas or Krebs' solution-gas partition coefficients at low temperature for isoflurane and enflurane were not available. The data were linearly fitted with the least square fit methods. All values are mean $\pm$ SEM $(n=4)$.

the relation between actual concentrations of volatile anesthetics in PSS and anesthetic concentrations (volume percentage) in the gas mixture should be theoretically linear. The anesthetic concentrations on the x -axis are displayed as volume percentage for the volatile anesthetic concentration-response relations.

## Calculation and Statistical Analysis

All results were expressed as the means $\pm$ standard error of the mean (SEM). The n denotes the number of preparations, and the number of animals is also noted.
The volatile anesthetic-induced relaxation in experiments with intact muscle at both temperatures was expressed as a percent change from the amplitude of high $\mathrm{K}^{+}$-induced contraction before application of the anesthetics, and the amplitude of volatile anestheticinduced vasoconstriction at $35^{\circ} \mathrm{C}$ was expressed relative to the amplitude of the $\mathbf{4 0} \mathrm{mm} \mathrm{K}{ }^{+}$-induced phasic contraction $(100 \%)$. The concentration-dependence of the volatile anesthetic-induced vasoconstriction in experiments with intact muscle at $22^{\circ} \mathrm{C}$ was not assessed, because the amount of $\mathrm{Ca}^{2+}$ in the intracellular $\mathrm{Ca}^{2+}$ store was probably not constant during "cumulative" application of volatile anesthetics in these experiments.
In experiments with $\beta$-escin-permeabilized muscle, the amplitude of the $\mathrm{Ca}^{2+}$-activated contraction at various time points in the presence and absence of volatile anesthetics was normalized to the amplitude of $\mathrm{Ca}^{2+}$ contraction 5 min after application of the activating solution. The effects of volatile anesthetics were then assessed by comparing the data in the presence of volatile anesthetics with the time control data.
The concentration-response data for volatile anesthetic effects or $\mathrm{Ca}^{2+}$-activated contractions were fitted according to a four parameter logistic model described by De Lean et al. ${ }^{45}$ The $\mathrm{EC}_{50}$ ( $50 \%$ effective concentration) or $\mathrm{IC}_{50}$ ( $50 \%$ inhibitory concentration) values were derived from the least-squares fit using the above equation.
Statistical analysis was made by an analysis of variance (one- or two-factor), Scheffé's F test, and Student's $t$ test (unpaired), where appropriate. A $P$ level of $<0.05$ was considered significant.

## Results

## Experiments with Intact Muscle

In intact muscle not treated with ryanodine, both halothane and enflurane generated transient contrac-
tions superimposed on the high $\mathrm{K}^{+}$-induced contractions at $22^{\circ} \mathrm{C}$ and at $35^{\circ} \mathrm{C}$ (figs. 2 and 3). Isoflurane generated similar transient contractions at $22^{\circ} \mathrm{C}$, but not at $35^{\circ} \mathrm{C}$ (figs. 2 and 3). The transient contractions caused by volatile anesthetics at both temperatures were followed by significant vasorelaxation (figs. 2 and 3). Ryanodine ( $10 \mu \mathrm{~m}$ ) abolished the volatile anes-

Fig. 2. (A) Control $143 \mathrm{~mm} \mathrm{~K}{ }^{+}$-induced contraction and effects of cumulative application $\left(0.25-5.0 \%, 22^{\circ} \mathrm{C}\right)$ of $(B)$ halothane, $(C)$ isoflurane, and (D) enflurane on $143 \mathrm{~mm} \mathrm{~K}^{+}$-induced contractions in the endothelium-denuded strips. All of the anesthetics evoked transient contractions, which were followed by sustained relaxation. Similar observations were made in several other strips ( $n=7-11$, six animals).

Fig. 3. Effects of various concentrations ( $0.125-5.0 \%$ ) of $(A)$ halothane, $(B)$ isoflurane, and ( $C$ ) enflurane on $40 \mathrm{~mm} \mathrm{~K}{ }^{+}$induced contractions in the endothe-lium-denuded strips at $35^{\circ} \mathrm{C}$. Halothane and enflurane produced vasoconstriction and vasodilation in a concentrationdependent manner, whereas isoflurane produced only vasodilation and not vasoconstriction. Similar observations were made in several other strips ( $\mathrm{n}=$ 6, six animals).

thetic-induced contractions in the presence of high $\mathrm{K}^{+}$at both temperatures (figs. 4-6). Significant differences were observed in the vasoconstricting effects at $35^{\circ} \mathrm{C}$ among the anesthetics, and the order of potency was halothane $>$ enflurane $>$ isoflurane (fig. 6). Ryanodine treatment did not significantly affect the phasic or tonic components of high $\mathrm{K}^{+}$-induced contractions at either temperature ( $P>0.05$ ).
The concentration-response curves for volatile an-esthetic-induced relaxation under various conditions (in the absence or presence of ryanodine; at either low or high temperature) are shown in figure 7. Two factor (concentration [volume percentage], anesthetic) analysis of variance revealed no significant difference in the vasorelaxation among the three volatile anesthetics under each condition. In addition, two-factor (concentration and treatment [with or without ryanodine]) analysis of variance showed no significant difference in the vasorelaxation produced by each anesthetic between the ryanodine-treated and untreated groups. The $\mathrm{IC}_{50}$ values for the vasodilating action of halothane, isoflurane, and enflurane at $22^{\circ} \mathrm{C}$ and $35^{\circ} \mathrm{C}$ in ryano-dine-treated and untreated strips are summarized in table 2.

## Experiments with $\beta$-Escin-Permeabilized Muscle

Application of various concentrations ( $0.1-100 \mu \mathrm{~m}$ ) of $\mathrm{Ca}^{2+}$ to the $\beta$-escin-treated strips generated the dosedependent contractions, and the $\mathrm{EC}_{50}$ value for the
$\mathrm{Ca}^{2+}$-tension relation derived from the least-squares fit with the logistic equation ${ }^{45}$ was $2.02 \mu$ M (fig. 8). The maximal $\mathrm{Ca}^{2+}$ activated contraction was $1.58 \pm 0.25$ times that of 143 mm K - induced maximal (phasic) contractions before permeabilization ( $\mathrm{n}=4$, four animals), suggesting satisfactory membrane permeabilization.
The effects of volatile anesthetics on $3 \mu \mathrm{~m}\left(\approx \mathrm{EC}_{50}\right)$ and $30 \mu \mathrm{M}$ (maximal) $\mathrm{Ca}^{2+}$-activated contractions were then examined. The $3 \mu \mathrm{M} \mathrm{Ca}^{2+}$ contraction was well maintained, whereas the $30 \mu \mathrm{M} \mathrm{Ca}^{2+}$ contraction slightly decayed (time control data, fig. 9). Comparison between the volatile anesthetic data and the time control data showed that halothane modestly, but significantly inhibited both $3 \mu \mathrm{M}\left(\approx \mathrm{EC}_{50}\right)$ and $30 \mu \mathrm{~m}$ (maximum) $\mathrm{Ca}^{2+}$-induced contractions (fig. 9). Enflurane slightly but significantly inhibited $3 \mu \mathrm{~m}$, but not $30 \mu \mathrm{~m}$ $\mathrm{Ca}^{2+}$ contractions. Isoflurane did not significantly inhibit either $3 \mu \mathrm{~m}$ or $30 \mu \mathrm{M} \mathrm{Ca}^{2+}$-induced contractions (fig. 9). All these anesthetics did not produce any significant vasoconstriction in membrane-permeabilized muscle strips that were pretreated with ionomycin to eliminate the intracellular $\mathrm{Ca}^{2+}$ stores.

## Discussion

The current study demonstrates that halothane, isoflurane, and enflurane all have a relaxing action on $\mathrm{K}^{+}$constricted small splanchnic resistance arteries. This

Fig. 4. Effects of ryanodine ( $10 \mu \mathrm{~m}$ ) on volatile anesthetic actions in the $143 \mathrm{~mm}{ }^{+}$-treated endothelium-denuded strips at $22^{\circ} \mathrm{C}$. ( $A$ and $B-b \sigma$ ) The $143 \mathrm{~mm} \mathrm{~K}{ }^{+}$contractions $(A)$ before and (B) after treatment with ryanodine. ( $B-b 1, B-b 2$, and $B-b 3$ ) Effects of cumulative application ( $0.25-5.0 \%$ ) of halothane, isoflurane, and enflurane on $143 \mathrm{~mm} \mathrm{~K}^{+}$contraction in the presence of ryanodine. Ryanodine had little effect on the 143 mm $\mathrm{K}^{+}$contraction or the anesthetic-induced vasodilation, but ryanodine eliminated the anesthetic-induced contractions that were observed in the absence of ryanodine (fig. 1). Similar observations were made in several other strips ( $n=5$, five animals).
action observed at clinically relevant anesthetic concentrations appears to be independent of endothelial or peripheral nerve activities, although this action may be influenced by anesthetic effects on endothelium or peripheral nerves in vivo. It is well established that $\mathrm{K}^{+}$-induced constrictions are caused by activation of voltage-gated $\mathrm{Ca}^{2+}$ channels and that these channels play a significant role in maintaining vascular tone in vivo. Thus, the effective concentrations of volatile an-
esthetics that inhibited the high $\mathrm{K}^{+}$-induced constrictions at physiologic temperature in these resistance arteries suggest that this "direct" vasodilating action of volatile anesthetics contributes to the hypotensive effects of these agents in vivo. No significant differences were observed in the direct vasodilating actions among the three anesthetics under any condition (with or without ryanodine; at either $22^{\circ} \mathrm{C}$ or $35^{\circ} \mathrm{C}$ ). Howeve异 because the minimum alveolar concentration of halo thane $(\approx 0.90 \%)$ is known to be lower than that oif isoflurane ( $1.38 \%$ ) or enflurane ( $1.40 \%$ ) in the rat, is ${\underset{\vec{\sigma}}{\overrightarrow{-}}}^{-1}$ flurane or enflurane would be a more potent vasodilat픃 than halothane in the high $\mathrm{K}^{+}$-stimulated splanchnie resistance artery at equivalent anesthetic concentr tions.

Halothane and enflurane slightly but significantly i咲: hibited the $\mathrm{Ca}^{2+}$-activated contractions in $\beta$-escin-pe ${ }^{-1}$ meabilized muscle, suggesting that the observed relaz.

Fig. 5. Effects of $5 \%$ of halothane, isoflurane, and enflurane on 40 mm K -induced contraction before $(A)$ and after $(B)$ ryanodine $(10 \mu \mathrm{M})$ treatment. Ryanodine had little effect on the 40 mm $\mathrm{K}^{+}$contraction or the volatile anesthetic-induced vasodilation but eliminated the volatile anesthetic-induced vasoconstrictions. Similar observations were made in other several strips ( $n=4$, four animals).

Fig. 6. Vasoconstricting action of volatile anesthetics in high $\mathrm{K}^{+}(\mathbf{4 0} \mathrm{mm})$-preconstricted strips before ( $A$ ) and after (B) treatment with ryanodine $(10 \mu \mathrm{M})$ at $35^{\circ} \mathrm{C}$. The measured amplitude ( $\mathbf{Y}$ ) of volatile anesthetic-induced vasoconstrictions (arrow) was normalized to the $\mathbf{4 0} \mathrm{mm} \mathrm{K}^{+}$-induced phasic contraction ( $100 \%$ ). Vasoconstriction disappears after ryanodine treatment. All values are mean $\pm$ SEM ( $\mathrm{n}=4-6$, four to six animals). ${ }^{*} P<0.05$ versus isoflurane group at each concentration. $\# \boldsymbol{P}<0.05$ versus enflurane group at each concentration.
ing actions of halothane and enflurane in the presence of high $\mathrm{K}^{+}$are attributable in part to inhibition of $\mathrm{Ca}^{2+}$ activation of contractile proteins. However, this effect was small relative to the amount of vasodilation observed in the high $\mathrm{K}^{+}$-constricted intact vessels, suggesting that the vasodilation is caused in large part by depression of increases in $\left[\mathrm{Ca}^{2+}\right]_{\mathrm{i}}$. At most, only $20 \%$ of the relaxing effect of halothane could be attributed to a direct inhibition of $\mathrm{Ca}^{2+}$ action on the contractile protein cascade; the rest of the effect is thus presumably caused by decreases in the rise of $\left[\mathrm{Ca}^{2+}\right]_{\mathrm{i}}$. The complete lack of effect of isoflurane on the $\mathrm{Ca}^{2+}$-activated contractions implies that its relaxing action is attributable almost completely to depression of the rise in $\left[\mathrm{Ca}^{2+}\right]_{\mathrm{i}}$. The small amount of inhibition of $\mathrm{Ca}^{2+}$-activated contractions by halothane in these small mesenteric arteries is consistent with the slight inhibition of maximal $\mathrm{Ca}^{2+}$ activated tension in membrane-permeabilized rabbit aortic tissue. ${ }^{5}$ The proposal that volatile anesthetics affect vascular tone by decreasing $\left[\mathrm{Ca}^{2+}\right]_{i}$ is consistent with recent investigations using fura-2-loaded vascular tissue in which halothane and isoflurane were shown to decrease both agonist- and high $\mathrm{K}^{+}$-induced increases in $\left[\mathrm{Ca}^{2+}\right]_{i} .{ }^{20}$ Previous studies have also demonstrated that halothane and isoflurane directly inhibit depolarization-activated long-lasting $\mathrm{Ca}^{2+}$ currents in vascular smooth muscle cells, ${ }^{22.23}$ suggesting that the $\left[\mathrm{Ca}^{2+}\right]$-reducing effects of volatile anesthetics result at least in part from inhibition of voltage-gated $\mathrm{Ca}^{2+}$ in-
flux. Finally, although still controversial, the increases in vascular smooth muscle cyclic guanosine monophosphate or cyclic adenosine monophosphate concentrations by anesthetics reported in some preparations, ${ }^{21.24}$ may play a role in altering $\mathrm{Ca}^{2+}$ sensitivity or affecting $\mathrm{Ca}^{2+}$ mobilization by stimulating $\mathrm{Ca}^{2+} \mathrm{ex}-$ trusion, $\mathrm{Ca}^{2+}$ uptake into the store or inhibiting voltagegated $\mathrm{Ca}^{2+}$ influx.
Although we did not directly compare the data for the vasodilating actions of volatile anesthetics between $22^{\circ} \mathrm{C}$ and $35^{\circ} \mathrm{C}$ because of the differences in experimental protocols (cumulative vs. single-dose application and 143 vs. 40 mm K ), the $\mathrm{IC}_{50}$ values (volume percentage) for the volatile anesthetic-induced inhi-

Fig. 7. Vasodilating action of volatile anesthetics in high $\mathrm{K}^{+}-$ treated endothelium-denuded strips in the presence (right) or absence (left) of ryanodine ( $10 \mu \mathrm{~m}$ ) at (A) $22^{\circ} \mathrm{C}$ and (B) $35^{\circ} \mathrm{C}$. No significant differences were observed in vasodilating action among three volatile anesthetics under each condition. The IC so $_{0}$ values for the vasodilating actions of volatile anesthetics under each condition are shown in table 2 . All values are displayed as mean $\pm$ SEM ( $n=7 \mathbf{- 1 1}$, six animals).
bitions of high $\mathrm{K}^{+}$-induced contraction were approximately three to six times greater at $35^{\circ} \mathrm{C}$ than at $22^{\circ} \mathrm{C}$. Assuming that the binding of an anesthetic to its active sites is determined by solution concentration (and not partial pressure), ${ }^{46}$ then some of this difference can be explained by the approximately 1.5 - to 2 -fold increase in the solubility of these anesthetics at $22^{\circ} \mathrm{C}$ compared with $35^{\circ} \mathrm{C}$ (fig. 1). However, with or without this correction, some of the differences in potency must be related to other temperature-sensitive factors such as the voltage-gated $\mathrm{Ca}^{2+}$ channels or enzyme activities involved in smooth muscle contraction.
In addition to the well-known $\mathrm{Ca}^{2+}$-dependent ex-citation-contraction coupling pathway, recent studies also indicate the existence of either a $\mathrm{Ca}^{2+}$-independent excitation-contraction coupling pathway or some mechanism(s) that increases $\mathrm{Ca}^{2+}$ sensitivity of contractile proteins in smooth muscle, particularly in response to receptor agonists. ${ }^{47-49}$ Although we did not demonstrate any substantial effect of volatile anesthetics on $\mathrm{Ca}^{2+}$ activation of contractile proteins, the effect(s) of the volatile anesthetics on the $\mathrm{Ca}^{2+}$-independent pathway can not be ruled out by the current study. Protein kinase C activation has been proposed to be involved in the $\mathrm{Ca}^{2+}$-independent excitation-contraction coupling or agonist-induced increase in $\mathrm{Ca}^{2+}$ sensitivity, ${ }^{3,42,47-49}$ and recent studies have suggested that volatile anesthetics may inhibit the protein kinase Cmediated $\mathrm{Ca}^{2+}$-independent pathway in canine tracheal smooth muscle. ${ }^{50}$ However, Ozhan et al. have recently reported that halothane and isoflurane lack effects on phorbol ester-induced protein kinase C-dependent contractions in isolated coronary arterial tissue. ${ }^{10} \mathrm{Be}$ cause vascular tone in vivo is largely dependent on release of norepinephrine, ${ }^{26}$ an agonist well known to increase protein kinase C activity by $\alpha_{1}$-adrenergic receptor activation, the effects of volatile anesthetics on the $\mathrm{Ca}^{2+}$-independent contraction mechanisms should

Fig. 8. $\mathrm{Ca}^{2+}$-tension relation in $\beta$-escin-permeabilized strips. (A) A 143 mm K -induced contraction in an intact strip followed by $\mathrm{Ca}^{2+}$-activated contraction in the same strip after $\beta$-escin permeabilization. (B) The $\mathrm{Ca}^{2+}$-tension relation in $\beta$-escinpermeabilized strips. The $\mathrm{EC}_{50}$ value derived from the leastsquares fit by the logistic equation ${ }^{45}$ was $2.02 \mu \mathrm{M}$. The magnitude of $\mathrm{Ca}^{2+}$-activated contractions was normalized to maximum ( $100 \mu \mathrm{~m}) \mathrm{Ca}^{2+}$-activated contraction, and all values represent mean $\pm$ SEM ( $n=5$, five animals).
be further investigated to clarify the volatile anesthetic vascular action in vivo.
All three anesthetics also have a significant transient vasoconstricting action that does not require the presence of endothelium or peripheral nerve activity and also occurs at clinically relevant (i.e., anesthetic) con-

Fig. 9. Effects of cumulative application (0.5-4.0\%) of halothane, isoflurane, and enflurane on $(A) 3 \mu \mathrm{M}\left(\approx \mathrm{EC}_{50}\right)$ and (B) $30 \mu \mathrm{M}$ (maximal) $\mathrm{Ca}^{2+}$-activated contractions in $\beta$-escin-permeabilized strips. Each anesthetic was cumulatively applied to the strips for a period of 2 min at each concentration after the $\mathrm{Ca}^{2+}$-activated contraction reached a plateau ( 5 min ). All values are mean $\pm$ SEM ( $\mathrm{n}=6-10$, six to eight animals). ${ }^{*} P<$ 0.05 versus time control (open circles) at each time point.
centrations. The vasoconstricting action was independent of the vasodilating action as evidenced by the finding that the relative potency of the anesthetics as vasoconstrictors was unrelated to their vasodilatory potency and the finding that ryanodine abolished the vasoconstricting action with little effect on volatile an-esthetic-induced vasodilation. In the high $\mathrm{K}^{+}$-constricted vessels, the observed vasoconstricting action was only transient, however, and was immediately followed by vasodilation as we have previously reported for halothane in the same vessels ${ }^{13}$ and for enflurane in rabbit small mesenteric arteries precontracted with adrenergic agonists. ${ }^{11}$ Thus, although vasoconstriction
did occur with clinically relevant concentrations of halothane and enflurane, the importance of this effect in altering splanchnic blood flow during anesthesia is uncertain. Of note, the vasoconstricting effect of isoflurane, which has not previously been reported, was observed only at $22^{\circ} \mathrm{C}$ and not at $35^{\circ} \mathrm{C}$, probably because isoflurane is considerably less potent at producing vasoconstriction. Because the solubility of isoflurane (as well as the other anesthetics) was lower at $35^{\circ} \mathrm{C}$ than at $22^{\circ} \mathrm{C}$, the apparent threshold for the vasoconstricting action of isoflurane observed at $22^{\circ} \mathrm{C}$ ( $2 \% \approx 1 \mathrm{~mm}$ ) was reached only with the maximum concentration studied at $35^{\circ} \mathrm{C}$ (i.e., $5 \%$ isoflurane; fig. 1). Therefore, the apparent inability of isoflurane to produce vasoconstriction at $35^{\circ} \mathrm{C}$ may have resulted from the different concentrations achieved in the buffer at $22^{\circ} \mathrm{C}$ compared with those at $35^{\circ} \mathrm{C}$. In addition, because the vasoconstricting action appears to involve $\mathrm{Ca}^{2+}$ release from intracellular stores (see below), the sequential-addition protocol that was used at $22^{\circ} \mathrm{C}$ did not permit an accurate analysis of the concentrationresponse relation at that temperature $\left(22^{\circ} \mathrm{C}\right)$. In conclusion, our data suggest that the vasoconstricting action might be a common characteristic of halogenated volatile anesthetics.
The ability of ryanodine to abolish the vasoconstricting action of volatile anesthetics in intact muscle, and the inability of volatile anesthetics to produce any significant contractions in ionomycin-treated $\beta$-escinpermeabilized muscle strongly suggest that the volatile anesthetics cause vasoconstriction by releasing $\mathrm{Ca}^{2+}$ from ryanodine-sensitive intracellular $\mathrm{Ca}^{2+}$ stores, and not by inducing $\mathrm{Ca}^{2+}$ influx or affecting $\mathrm{Ca}^{2+}$ sensitivity. This is consistent with our previous reports in which the halothane- or enflurane-induced vasoconstricting effects were independent of extracellular $\mathrm{Ca}^{2+}$ concentration and were blocked by ryanodine. ${ }^{12,13}$ Similar ry-anodine-sensitive vasoconstricting effects of halothane and enflurane were recently reported in canine mesenteric artery. However, the authors suggested that, in addition to $\mathrm{Ca}^{2+}$ release from intracellular stores in smooth muscle, vasoconstriction in those vessels may also involve a change in $\mathrm{Ca}^{2+}$ sensitivity or an endothelium effect. ${ }^{14}$ Although our data indicate that an increase in $\mathrm{Ca}^{2+}$ sensitivity is not involved, we did not examine their endothelium dependence. A ryanodinesensitive intracellular $\mathrm{Ca}^{2+}$ store has recently been documented in endothelial cells, ${ }^{51,52}$ which may play an important role in the regulation of endothelial function. ${ }^{53.54}$ Therefore, it might be possible that volatile
anesthetics affect endothelial function by causing a change in the integrity of the endothelial ryanodinesensitive $\mathrm{Ca}^{2+}$ store, and this endothelial action may modify the volatile anesthetic action on vascular smooth muscle.
The observed order of potency for the $\mathrm{Ca}^{2+}$ releasing effects of volatile anesthetics from the ryanodine-sensitive store (halothane $>$ enflurane $>$ isoflurane) is consistent with previous studies in which halothane and enflurane, but not isoflurane, open $\mathrm{Ca}^{2+}$ release channels of cardiac sarcoplasmic reticulum ${ }^{55,56}$ and stimulate $\left[{ }^{3} \mathrm{H}\right]$ ryanodine binding to cardiac sarcoplasmic reticulum. ${ }^{57}$ However, only isoflurane, and not halothane or enflurane, stimulated $\left[{ }^{3} \mathrm{H}\right]$ ryanodine binding to skeletal ryanodine receptor. ${ }^{57}$ The cardiac ryanodine receptor gene (RYR2) or skeletal ryanodine receptor gene (RYR1) is known to be different from vascular smooth muscle ryanodine receptor gene (RYR3), which is also expressed in brain or lung epithelial cells. ${ }^{58}$ Therefore, the RYR3 presumed present in our tissue appears to resemble RYR2 more than it does RYR1.
In conclusion, halothane, isoflurane, and enflurane have direct vasoconstricting and vasodilating actions that are independent of endothelial or nerve terminal activities in rat small mesenteric arteries. Although the clinical relevance of the transient vasoconstricting action is uncertain, the vasodilating action at clinically relevant concentrations suggests that it may contribute significantly to the vascular effects of volatile anesthetics in vivo. Compared with their vasodilating actions in high $\mathrm{K}^{+}$-constricted vessels, the relatively small effects of these anesthetics on $\mathrm{Ca}^{2+}$-induced contractions in $\beta$-escin-permeabilized muscle suggest that these anesthetics have little or no effect on $\mathrm{Ca}^{2+}$ activation of contractile proteins. Thus, the direct vasodilation in high $\mathrm{K}^{+}$-treated vascular smooth muscle must be largely explained by effects on intracellular $\mathrm{Ca}^{2+}$ mobilization. The "direct" vasoconstricting action of volatile anesthetics depends on the $\mathrm{Ca}^{2+}$ release from the ryanodine-sensitive $\mathrm{Ca}^{2+}$ store and does not appear related to $\mathrm{Ca}^{2+}$ influx or any change in the $\mathrm{Ca}^{2+}$ sensitivity of contractile proteins. This is the first investigation to demonstrate volatile anesthetic action on $\mathrm{Ca}^{2+}$ activation of contractile proteins in the resistance arteries that are important in the regulation of systemic blood pressure and splanchnic blood flow.

The authors are grateful to Professor Alex S. Evers (Department of Anesthesiology, Washington University) and Professor Shosuke Tak-
ahashi (Department of Anesthesiology, Kyushu University) for their continuous encouragement and helpful comments; to Dr. Masamitsu Hatakenaka (Department of Clinical Pharmacology, Kyushu University), Dr. Takeo Itoh (Department of Pharmacology, Kyushu University), and Dr. Junji Nishimura (Division of Molecular Cardiology, Research Institute of Angiocardiology, Kyushu University) for their critical advice on the preparation of solutions for experiments with membrane-permeabilized muscle; and to Sandra Leal and Gail Maher (Department of Anesthesiology, Washington University) for their kind help with the gas chromatography experiments.

## Appendix

The binding constants used to calculate the compo－ sitions of the solutions for the experiments with mem－
brane－permeabilized muscle are as follows，where ATP $=$ adenosine triphosphate and $\mathrm{CrP}=$ creatinine phos－ phate；other abbreviations are defined in main text． $\left[\mathrm{HEGTA}^{3-}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{EGTA}^{4-}\right]=2.88 \times 10^{9},\left[\mathrm{H}_{2} \mathrm{EGTA}^{2-}\right] /$ $\left[\mathrm{H}^{+}\right]\left[\mathrm{HEGTA}^{3-}\right]=7.08 \times 10^{8}, \quad\left[\mathrm{H}_{3} \mathrm{EGTA}^{-}\right] /$ $\left[\mathrm{H}^{+}\right]\left[\mathrm{H}_{2} \mathrm{EGTA}^{2-}\right]=4.79 \times 10^{2},\left[\mathrm{H}_{4} \mathrm{EGTA}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{H}_{3} \mathrm{EGTA}^{-}\right]$ $=1.00 \times 10^{2} ;\left[\mathrm{HATP}^{3-}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{ATP}^{4-}\right]=8.91 \times 10^{6}{ }_{8}$ $\left[\mathrm{H}_{2} \mathrm{ATP}^{2-}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{HATP}^{3-}\right]=1.12 \times 10^{4},\left[\mathrm{H}_{3}\right.$ ATP $\left.^{-}\right]$房 $\left[\mathrm{H}^{+}\right]\left[\mathrm{H}_{2} \mathrm{ATP}^{2-}\right]=1.00 \times 10^{1},\left[\mathrm{H}_{4} \mathrm{ATP}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{H}_{3}\right.$ ATP $\left.^{-}\right]=$ $1.00 \times 10^{1} ;\left[\mathrm{CaEGTA}^{2-}\right] /\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{EGTA}^{4-}\right]=5.01 \times 10^{10} \frac{2}{\circ}$ $\left[\mathrm{CaHEGTA}^{-}\right] /\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{HEGTA}^{3-}\right]=2.14 \times 10^{5} ;\left[\mathrm{CaATP}^{2-}\right]$ $\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{ATP}^{4-}\right]=9.55 \times 10^{3},\left[\mathrm{CaHATP}^{-}\right] /[\mathrm{Ca}]\left[\mathrm{HATP}^{3-}\right]$ 喜 $6.31 \times 10^{1} ;[\mathrm{CaCrP}] /\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{CrP}^{2-}\right]=1.41 \times 10^{1 \stackrel{W}{\omega}}$
 HEGTA $\left.^{-}\right] /\left[\mathrm{Mg}^{2+}\right]\left[\mathrm{HEGTA}^{3-}\right]=2.34 \times 10^{3} ;\left[\mathrm{MgATP}^{2-}\right]$ $\left[\mathrm{Mg}^{2+}\right]\left[\right.$ ATP $\left.^{4-}\right]=2.11 \times 10^{4},\left[\mathrm{MgHATP}^{-}\right] /\left[\mathrm{Mg}^{2+}\right]\left[\mathrm{HATP}^{3-}{ }^{-\omega}\right.$ $=5.50 \times 10^{2} ;[\mathrm{MgCrP}] /\left[\mathrm{Mg}^{2+}\right]\left[\mathrm{CrP}^{2-}\right]=2.0 \times 10^{13}$ $[\mathrm{HCrP}] /\left[\mathrm{H}^{+}\right]\left[\mathrm{CrP}^{2-}\right]=3.80 \times 10^{4},\left[\mathrm{H}_{2} \mathrm{CrP}\right] /\left[\mathrm{H}^{+}\right]\left[\mathrm{CrP}^{2-}\right.$ 量 $=5.01 \times 10^{2} ;\left[\mathrm{KATP}^{3-}\right] /\left[\mathrm{K}^{+}\right]\left[\mathrm{ATP}^{4-}\right]=7.94,\left[\mathrm{~K}_{2} \mathrm{ATP}^{2-}\right]_{\%_{o}^{\circ}}$ $\left[\mathrm{K}^{+}\right]\left[\mathrm{KATP}^{3-}\right]=0.6,\left[\mathrm{KHATP}^{2-}\right] /\left[\mathrm{K}^{+}\right]\left[\mathrm{HATP}^{3-}\right]=0.6 \mathrm{G}_{\mathrm{Q}}^{\mathbf{\circ}}$ $\left[\mathrm{NaATP}^{3-}\right] /\left[\mathrm{Na}^{+}\right]\left[\mathrm{ATP}^{4-}\right]=8.8,\left[\mathrm{Na}_{2} \mathrm{ATP}^{2}\right] /\left[\mathrm{Na}^{+}\right]\left[\mathrm{NaATP}^{3} \frac{\text { 殔 }}{}\right.$ $=8.5,\left[\mathrm{NaHATP}^{2-}\right] /\left[\mathrm{Na}^{+}\right]\left[\mathrm{HATP}^{3-}\right]=5.0 ;\left[\mathrm{H} \mathrm{PIPES}^{-}\right]$ $\left[\mathrm{H}^{+}\right]\left[\mathrm{PIPES}^{2-}\right]=6.31 \times 10^{6}$ ．

[^1]:    The gas concentrations (\%) are expressed as mean $\pm$ SEM ( $\mathrm{n}=4-11,6$ animals). The values in parentheses represent the mean concentrations in high $\mathrm{K}^{+}$containing physiologic salt solution expressed in mm . These values were calculated from the data shown in figure 1.
